Packings of frictionless athermal particles that interact only when they overlap experience a jamming transition as a function of packing density. Such packings provide the foundation for the theory of jamming. This theory rests on the observation that, despite the multitude of disordered configurations, the mechanical response to linear order depends only on the distance to the transition. We investigate the validity and utility of such measurements that invoke the harmonic approximation, and show that there is a well-defined linear regime in the thermodynamic limit.

I. INTRODUCTION

The harmonic approximation of an energy landscape is the foundation of much of solid state physics [1]. Calculations that invoke this simplifying assumption are said to be in the linear regime and are responsible for our understanding of many material properties such as sound propagation and the elastic or vibrational response to small perturbations [1, 2]. While the harmonic approximation is not exact and breaks down for large perturbations, the existence of a linear regime is essential to our understanding of ordered solids.

While the lack of any periodic structure has long made amorphous materials difficult to study, the past decade has seen significant progress towards uncovering the origin of commonality in disordered solids by way of the jamming scenario [3]. Specifically, numerous studies of the jamming transition of athermal soft spheres have exploited the harmonic approximation to reveal a non-equilibrium phase transition [3–11]. Near this jamming transition, the shape of the landscape near each minimum is essentially the same within the harmonic approximation – for example, the distribution of curvatures around the minimum, which is directly related to the density of normal modes of vibration, is statistically the same for the vast majority of energy minima. As a result, linear response properties such as the elastic constants can be characterized by a single property of the minimum, such as its energy, pressure or contact number, which quantifies the distance from the jamming transition for that state. This powerful property forms the basis of the jamming scenario, which has been shown to explain similarities in the mechanical and thermal properties of many disordered solids.

However, the jamming scenario is based on systems with finite-ranged potentials. It was pointed out by Schreck *et al.* [12] that for such potentials, breaking and forming contacts are a source of nonlinearity and they concluded that the harmonic approximation should

not be valid for disordered sphere packings in the large-system limit even for infinitesimal perturbations. Without a valid linear regime, quantities like the density of vibrational modes and elastic constants are ill defined. Thus, their claim calls into question much of the recent progress that has been made in understanding the nature of the jammed solid.

In this paper, we examine the effect of nonlinearities in jammed sphere packings. In Sec. II we define the harmonic approximation, discuss two distinct sources of nonlinearities that can arise in jammed particulate systems and describe the various limits in which they should be understood. In Sec. III, we show that packings at densities above the jamming transition have a linear regime in the thermodynamic limit. In Sec. IV we discuss finite-amplitude vibrations. Finally, we conclude in Sec. V with a discussion of our results and their implications for the jamming scenario.

One somewhat counterintuitive result is that for intrinsically anharmonic potentials such as the Hertzian potentials, contact nonlinearities do not affect the harmonic approximation in the limit of small displacements. Such nonlinearities only pose a danger for Hookian repulsions, but even in that case, there is a well-defined linear regime in the thermodynamic limit for any density above the transition, contrary to the conclusions of Schreck *et al.* [12]. Thus, our results show that the harmonic approximation is on footing that is as firm for disordered solids as it is for ordered solids.

II. THE HARMONIC APPROXIMATION AND ITS LEADING NONLINEAR CORRECTIONS

We consider athermal packings of N soft spheres in d dimensions that interact with the pair potential

$$V(r) = \begin{cases} \frac{\epsilon}{\alpha} \left(1 - \frac{r}{\sigma}\right)^\alpha & \text{if } r < \sigma \\ 0 & \text{if } r \geq \sigma. \end{cases} \quad (1)$$

Here, r is the center-to-center distance between two particles, σ is the sum of the particles' radii, $\epsilon \equiv 1$ sets the energy scale, and $\alpha \geq 2$ determines the power law of the

* cpgoodri@sas.upenn.edu

interactions. Such packings jam when the packing fraction ϕ exceeds a critical density ϕ_c , and we will use the excess packing fraction, $\Delta\phi \equiv \phi - \phi_c$, as a measure of the distance to jamming.

The harmonic approximation is obtained from the expansion of the total energy:

$$U \equiv \sum_{\text{contacts}} V(r) \quad (2)$$

$$= U^0 - F_i^0 u_i + \frac{1}{2} D_{ij}^0 u_i u_j + \frac{1}{3!} T_{ijk}^0 u_i u_j u_k + \dots \quad (3)$$

where the indices i, j, k run from 1 to dN and index the d coordinates of each of the N particles, and the dN -dimensional vector \vec{u} represents some collective displacement about the initial positions. It will be useful to denote the magnitude of \vec{u} as δ and the direction as \hat{u} , so that $\vec{u} = \hat{u}\delta$. U^0 is the energy of the initial system. \vec{F}^0 gives the net force component on every particle, $F_i^0 = -\frac{\partial U}{\partial u_i}|_{\vec{u}=0}$, which vanishes if the system is mechanically stable. The dynamical matrix D^0 is given by the second derivative of the energy, $D_{ij}^0 = \frac{\partial^2 U}{\partial u_i \partial u_j}|_{\vec{u}=0}$, and the tensors T^0 , etc. are given by higher-order derivatives. The “0” superscripts emphasize that the derivatives are evaluated at $\vec{u} = 0$.

The mechanical response of an athermal system of particles is governed by the equations of motion,

$$m_i \ddot{u}_i = F_i(\vec{u}), \quad (4)$$

where m_i is the particle mass and $\vec{F}(\vec{u})$ is the vector of instantaneous forces, *i.e.*, evaluated at \vec{u} . Since $D_{ij}(\vec{u}) = -\frac{\partial F_i(\vec{u})}{\partial u_j}$, where $D(\vec{u})$ is the instantaneous dynamical matrix, this force is generically given by

$$F_i(\vec{u}) = - \int D_{ij}(\vec{u}) du_j, \quad (5)$$

where the integral follows the trajectory of the particles from the mechanically stable minima at $\vec{u} = 0$ to the current configuration.

A mechanically stable system is said to be in the linear regime if the harmonic approximation

$$U - U^0 \approx \frac{1}{2} D_{ij}^0 u_i u_j \quad (6)$$

is accurate enough to describe the phenomenon of interest. Under this assumption, the dynamical matrix is constant and the equations of motion become linear:

$$m_i \ddot{u}_i = -D_{ij}^0 u_j. \quad (7)$$

The solutions to Eq. (7) are called the normal modes of vibration and are among the most studied quantities in solid state physics.

A. Microscopic vs. bulk response

Importantly, the extent of the linear regime depends on the quantity one wishes to measure; Eq. (7) might

accurately describe one phenomena but fail to describe another. Thus, it is important to clarify the quantities of interest [13]. For crystalline solids, the linear approximation is often used to calculate bulk thermal and mechanical properties, such as the elastic moduli and thermal conductivity. However, it is typically *not* used to predict exact microscopic details over long times. If one were to perturb a system along one of its vibrational modes, for example, the linear equations of motion predict simple oscillatory motion confined to the direction of that mode. However, this is not what happens, since even very slight nonlinearities can cause energy to gradually leak into other modes [1].

Clearly, the linear theory fails to describe such microscopic details, except for the very special case where the harmonic approximation is *exact*, and one would not expect disordered sphere packings to be an exception. However, linear response has had tremendous success in predicting the *bulk* mechanical and thermal properties of crystals. It is these bulk linear quantities, not the details of microscopic response, that are central to the theory of jamming, and will thus be the focus of the remainder of this paper.

We will primarily be concerned with determining whether the harmonic approximation is valid in the limit of infinitesimal displacements, δ . In other words, we will be asking whether δ can be made small enough so that Eq. (7) accurately describes bulk response. If so, then linear quantities such as the density of states or the elastic constants are well-defined. While experimental measurements in real systems necessarily involve nonzero displacements, our focus on the limit $\delta \rightarrow 0$ will reveal whether the lowest-order behavior can be ascertained from the harmonic approximation.

To understand the breakdown of the harmonic approximation, it is useful to separate nonlinear corrections into two distinct categories, as outlined below.

B. Expansion nonlinearities

Expansion nonlinearities are those which are described by the higher order terms in Eq. (3), and can thus be understood from derivatives of the total energy at the energy minimum. However, provided the quadratic term $\frac{1}{2} D_{ij}^0 u_i u_j$ is positive in all directions, δ can always be made small enough so that the higher order terms become negligible [14]. At the jamming transition, *i.e.* $\Delta\phi = 0$, the quadratic term vanishes in some directions in configurational space, so the harmonic approximation fails. Away from the jamming transition, *i.e.* $\Delta\phi > 0$, however, the quadratic term is indeed positive in all directions. (In all our calculations, we remove rattlers, which correspond to zero-frequency modes, so that the dynamical matrix only contains particles that are part of the jammed network.) Thus, although expansion nonlinearities can be important and even dominate certain phenomena, they cannot prevent a system from having a

FIG. 1. Illustration of nonlinearities for packings of $N = 64$ particles with Hookian spring-like interactions ($\alpha = 2$, top) and Hertzian interactions ($\alpha = 2.5$, bottom). Both systems are at a pressure of 10^{-2} . The red data shows the total energy $U - U^0$ as the system is displaced by an amount δ along its lowest non-zero mode. The black line gives the prediction of the harmonic approximation, see Eq. (6). The difference between $U - U^0$ and the predicted energy is shown by the blue data, and the blue line has a slope of 3. The vertical dashed line represents the value of δ where the contact network first changes, and the green data gives the magnitude of the change in energy due to contact changes.

linear regime for $\Delta\phi > 0$.

An easy way to observe expansion nonlinearities is to displace a system by an amount δ in some direction \hat{u} and measure the energy as a function of δ . $U - U^0$ can then be compared to the prediction of the harmonic approximation given by Eq. (6). A typical example of this is shown in Fig. 1 for jammed packings of particles with Hookian spring-like interactions ($\alpha = 2$, top) and Hertzian interactions ($\alpha = 2.5$, bottom). The corrections to the harmonic approximation have clear cubic behavior at small δ . Note that they are present when $\alpha = 2$: even a spring network has expansion nonlinearities in dimension $d > 1$. This can be seen from Eq. (3) by writing the tensor T_{ijk}^0

as

$$\begin{aligned} T_{ijk}^0 &\equiv \sum_{\text{contacts}} \frac{\partial^3 V(r)}{\partial r_i \partial r_j \partial r_k} \\ &= \sum_{\text{contacts}} t \left(\frac{\partial r}{\partial r_i} \frac{\partial r}{\partial r_j} \frac{\partial r}{\partial r_k} \right) - f \left(\frac{\partial^3 r}{\partial r_i \partial r_j \partial r_k} \right), \quad (8) \\ &\quad + k \left(\frac{\partial^2 r}{\partial r_i \partial r_k} \frac{\partial r}{\partial r_j} + \frac{\partial^2 r}{\partial r_j \partial r_k} \frac{\partial r}{\partial r_i} + \frac{\partial^2 r}{\partial r_i \partial r_j} \frac{\partial r}{\partial r_k} \right) \end{aligned}$$

where $f \equiv -\frac{\partial V(r)}{\partial r}$, $k \equiv \frac{\partial^2 V(r)}{\partial r^2}$, and $t \equiv \frac{\partial^3 V(r)}{\partial r^3}$, and the terms $\frac{\partial r}{\partial r_i}$, $\frac{\partial^2 r}{\partial r_i \partial r_j}$ and $\frac{\partial^3 r}{\partial r_i \partial r_j \partial r_k}$ are generically nonzero.

C. Contact nonlinearities

Unlike a true spring network, contacts in a sphere packing are allowed to form and break. Since the total energy is a sum over particles in contact, nonlinearities arise when the contact network is altered. Such *contact nonlinearities* cannot be understood from derivatives of the energy at the minimum. For pair interactions of the form of Eq. (1), the energy expansion of Eq. (3) is not analytic when contacts form or break and the second derivative is discontinuous if $\alpha \leq 2$.

For the two systems in Fig. 1, the green data show the magnitude of the change in energy due to altered contacts. The vertical dashed lines indicate the minimum displacement magnitude, δ_c , required to change the contact network. While the value of δ_c varies greatly depending on the realization and displacement direction, Schreck *et al.* [12] showed that $\langle \delta_c \rangle \rightarrow 0$ in two important limits. As the number of particles increases, so too does the number of contacts and thus the probability that *some* contact is on the verge of forming or breaking must also increase. Similarly, all contacts are on the verge of breaking in a marginally jammed system at $\Delta\phi = 0$. Therefore, the onset amplitude δ_c of contact nonlinearities vanishes as either $N \rightarrow \infty$ or $\Delta\phi \rightarrow 0$ [12].

D. Important limits

Due to the existence of a phase transition at the jamming point, the limits $N \rightarrow \infty$ and $\Delta\phi \rightarrow 0$ are of particular interest. When studying the leading order mechanical properties of a solid, one also considers the limit of infinitesimal displacements, *i.e.* $\delta \rightarrow 0$. However, the order at which these limits are taken is important. For example, Schreck *et al.* showed that $\delta_c > 0$ for finite $\Delta\phi$ and N [12], so there is a perfectly well-defined linear regime if $\delta \rightarrow 0$ is the first limit taken. This is the standard order of limits taken, for example, in the harmonic theory of crystalline solids [15].

We already saw that expansion nonlinearities can occur if one considers taking the limit $\Delta\phi \rightarrow 0$ before $\delta \rightarrow 0$, and the importance of these nonlinearities is emphasized

in, for example, Refs. [5, 16–18]. Furthermore, Schreck *et al.* [12, 19] showed that contact nonlinearities will also be present in this case, regardless of system size. Thus, there is no linear regime at $\Delta\phi = 0$. This result was generalized to finite temperatures by Ikeda *et al.* [18] and Wang and Xu [20], who independently showed that the linear regime breaks down above a temperature T^* when $\Delta\phi > 0$.

Finally, for athermal systems above the jamming transition ($\Delta\phi > 0$), contact nonlinearities are unavoidable if we take the limit $N \rightarrow \infty$ before $\delta \rightarrow 0$. Nevertheless, we will show next that there is still a well-defined linear regime in this case.

III. PROOF OF A LINEAR REGIME IN THE THERMODYNAMIC LIMIT

In this section, we will show that there is always a well-defined linear regime in the thermodynamic limit whenever $\Delta\phi > 0$. We will assume that $T = 0$ and that the limit $N \rightarrow \infty$ is taken before the limit $\delta \rightarrow 0$ so that any infinitesimal displacement $\delta|\hat{u}\rangle$ changes the contact network, leading to contact nonlinearities. As discussed above, we will primarily be concerned with establishing the existence of a linear regime for bulk quantities, such as the elastic constants or heat capacity. Since these quantities are described by the density of vibrational modes, $D(\omega)$, it will suffice to show that $D(\omega)$ is insensitive to nonlinear corrections in the limit $\delta \rightarrow 0$. This is not the case for microscopic quantities, such as the precise time evolution following a particular perturbation to a particle or group of particles, which can be highly sensitive to microscopic details that have no noticeable bulk effect.

We will first present a perturbation argument to show that changes to $D(\omega)$ due to contact nonlinearities vanish in the thermodynamic limit as N^{-1} [13]. This result is independent of potential and shows that linear response holds for bulk quantities. We will then present a far simpler argument, based on the continuity of the dynamical matrix for potentials with $\alpha > 2$, that shows a clear linear regime for *both* bulk and microscopic quantities [13]. Our results can be reconciled with those of Schreck *et al.* [12, 19] because they only look at microscopic quantities of relatively small packings close to the transition.

A. Validity of bulk linear response

Here, we will construct a perturbation theory to describe the effect of contact nonlinearities on the vibrational modes and their corresponding frequencies. We will begin by considering only a single altered contact and then extend the results to the case of many altered contacts. We will assume that $N^{-1} \ll \delta \ll 1$ so that contact nonlinearities are unavoidable but all expansion nonlinearities can be ignored.

Let ΔD be the change in the dynamical matrix as a result of the change of a single contact, so that the new dynamical matrix is $\tilde{D} = D^0 + \Delta D$. Note that ΔD is highly sparse with only $4d^2$ non-zero elements, where d is the dimensionality. We now consider the effect of the perturbation ΔD on the eigenmodes of D^0 (*i.e.*, the original normal modes of vibration).

1. Extended modes

Let $|\hat{e}_n\rangle$ and ω_n^2 be the n th eigenmode and eigenvalue of D^0 , respectively. If a normalized mode is extended, then every component will be of order $N^{-1/2}$. For now, we will assume that all modes are extended; the extension of the argument to localized modes is discussed below. The change in the n th eigenvalue of D^0 can be described by the expansion

$$\begin{aligned} \Delta\omega_n^2 &\equiv \tilde{\omega}_n^2 - \omega_n^2 \\ &= \langle \hat{e}_n | \Delta D | \hat{e}_n \rangle + \sum_{m \neq n} \frac{|\langle \hat{e}_m | \Delta D | \hat{e}_n \rangle|^2}{\omega_n^2 - \omega_m^2} + \dots \end{aligned} \quad (9)$$

where $\tilde{\omega}_n^2$ is the eigenvalue of \tilde{D} and $\langle \hat{e}_n | \Delta D | \hat{e}_n \rangle \sim \langle \hat{e}_m | \Delta D | \hat{e}_n \rangle \sim N^{-1}$ because the modes are extended and ΔD is highly sparse. While the first-order term clearly scales as N^{-1} , the higher-order terms depend on the mode spacing as well. Since the probability distribution of eigenvalues does not depend on N , the average eigenvalue spacing is proportional to N^{-1} . If we assume that

$$|\omega_n^2 - \omega_m^2| > N^{-1}, \quad (10)$$

then all higher order terms in Eq. (9) are at most proportional to N^{-1} .

However, just because the average mode spacing is of order N^{-1} does not mean that *all* modes are separated by N^{-1} . To account for the possibility of, for example, two nearly degenerate modes, $|\hat{e}_n\rangle$ and $|\hat{e}_m\rangle$, that do not satisfy Eq. (10), we explicitly solve the degenerate perturbation problem given by

$$V \equiv \begin{pmatrix} \langle \hat{e}_n | \Delta D | \hat{e}_n \rangle & \langle \hat{e}_m | \Delta D | \hat{e}_n \rangle \\ \langle \hat{e}_n | \Delta D | \hat{e}_m \rangle & \langle \hat{e}_m | \Delta D | \hat{e}_m \rangle \end{pmatrix} \quad (11)$$

that treats the coupling between $|\hat{e}_n\rangle$ and $|\hat{e}_m\rangle$. The eigenvalues of V give the full corrections to ω_n^2 and ω_m^2 from their mutual interaction with the perturbation ΔD . The coupling with the other modes is given by Eq. (9), where terms involving the two nearly degenerate modes are omitted.

Since the elements of V are all proportional to N^{-1} , so too are its eigenvalues. We have already shown that the non-degenerate effect is at most order N^{-1} , so the full effect of the perturbation on all eigenvalues ω_n^2 must vanish in the thermodynamic limit.

We can construct a similar expansion for the eigenvectors. The non-degenerate case is given by

$$|\tilde{e}_n\rangle = |\hat{e}_n\rangle + \sum_{m \neq n} \frac{\langle \hat{e}_m | \Delta D | \hat{e}_n \rangle}{\omega_n^2 - \omega_m^2} |\hat{e}_m\rangle + \dots \quad (12)$$

while the coupling between nearly degenerate modes that do not satisfy Eq. (10) is given by the eigenvectors of V . As should be expected, the eigenvectors of V can cause considerable mixing between the nearly degenerate modes. Furthermore, the coefficients in front of $|\hat{e}_m\rangle$ in Eq. (12) do not vanish when $|\omega_n^2 - \omega_m^2|$ is of order N^{-1} . Thus, an eigenmode can mix with the few modes nearest in frequency, but the eigenvalue difference between such modes vanishes as N^{-1} . In the thermodynamic limit, modes that are able to mix must already be degenerate, so distinguishing between them is meaningless. It is clear that the mode mixing caused by the perturbation ΔD cannot change the spectral density in the thermodynamic limit.

2. Localized modes

We will now consider the effect of localized modes. We will show that localized modes that overlap with the altered contact can change substantially, but their presence does not affect the extended modes. Furthermore, since the number of modes that are localized to a given region cannot be extensive, the total density of states will be unaffected. Although we will consider modes that are completely localized to a few particles, the arguments can be easily applied to quasi-localized modes by including appropriate higher-order corrections.

If a localized mode does not overlap with the altered contact, then the matrix elements in Eqs. (9) and (12) involving that mode are zero. In this trivial case, the localized mode is unchanged and does not couple to any other modes. However, if a localized mode *does* overlap with the altered contact, then the matrix elements coupling it to an extended mode are proportional to $N^{-1/2}$ (not N^{-1} , as it is for the extended modes).

In this case, we cannot use the non-degenerate perturbation theory of Eqs. (9) and (12). For instance, there is always a k th order term in Eq. (9) that is proportional to $N^{-1}/|\omega_n^2 - \omega_m^2|^{k-1}$ and does not converge unless $|\omega_n^2 - \omega_m^2| \gg \mathcal{O}(N^{-1/(k-1)})$. Therefore, we must treat the interaction between the localized mode and all nearby extended modes by solving the degenerate problem.

Let ω_l^2 be the the eigenvalue of a localized mode, and let the indices s and t run over the set of ρN modes that satisfy

$$|\omega_{s,t}^2 - \omega_l^2| < c$$

where c is some small constant. Note that the localized mode is among those spanned by s and t . To diagonalize

the symmetric perturbation matrix

$$V_{st} \equiv \langle \hat{e}_s | \Delta D | \hat{e}_t \rangle, \quad (13)$$

note that the dynamical matrix can be written [21] as

$$D = A F^{-1} A^T.$$

Here, A is the equilibrium matrix and has dN rows and N_c columns, where N_c is the number of contacts, N is the number of particles and d is the dimensionality. F is the diagonal flexibility matrix and has N_c elements $F_{ii} = 1/k_i$, where k_i is the stiffness of the i th contact. When $N_c = 1$, as is the case for our perturbation matrix ΔD , the equilibrium matrix becomes a vector, $A \rightarrow |A\rangle$, and the flexibility matrix becomes the scalar $1/k$. We can now write the matrix elements as

$$\begin{aligned} V_{st} &= \langle \hat{e}_s | \left(|A\rangle k \langle A| \right) | \hat{e}_t \rangle \\ &= a_s a_t, \end{aligned} \quad (14)$$

where $a_s = k^{1/2} \langle A | \hat{e}_s \rangle$ and $\langle A | \hat{e}_s \rangle$ is simply the projection of the original eigenvector $|\hat{e}_s\rangle$ onto the broken contact. Note that for extended modes, the magnitude of a_s scales as

$$a_s \sim N^{-1/2} \quad (15)$$

while for localized modes

$$a_l \sim 1. \quad (16)$$

The eigenvalues and eigenvectors of the ρN by ρN matrix V_{st} can be solved exactly, with the following results.

A matrix of the form of Eq. (14) has only one non-zero eigenvalue,

$$\Delta\omega_l^2 = a_l^2 + \sum_{s \neq l} a_s^2, \quad (17)$$

which gives the change in energy of the localized mode and does not vanish in the thermodynamic limit. This is not surprising given the drastic overlap between the mode and the altered contact. Similarly, the corresponding eigenvector gives the coupling from the extended modes:

$$|\tilde{e}_l\rangle = |\hat{e}_l\rangle + \sum_{s \neq l} \frac{a_s}{a_l} |\hat{e}_s\rangle. \quad (18)$$

From the scalings of a_s and a_l , there is a $N^{-1/2}$ contribution to $|\tilde{e}_l\rangle$ from each of the ρN extended modes, the elements of which also scale like $N^{-1/2}$. Therefore, $|\tilde{e}_l\rangle$ becomes at least partially extended if $\sum_{s \neq l} a_s^2 > 0$.

Thus, forming or breaking a single contact can significantly change the eigenvalue of localized modes that happen to overlap with the altered contact. However, since the density of such modes vanishes as N^{-1} , the effect on the density of states is negligible. Furthermore, note that if the initial displacement $|u\rangle$ is along a localized

mode, then there is always a finite displacement amplitude δ_c before the first contact change and so contact nonlinearities can be avoided.

To understand the effect of localized modes on the extended modes, we see that all other eigenvalues of V_{st} are zero:

$$\Delta\omega_s^2 = 0 \quad \text{for all } s \neq l \quad (19)$$

This implies that the frequency of an extended mode does not change due to the presence of a localized mode. However, there is a small correction to the mode itself,

$$|\tilde{e}_s\rangle = |\hat{e}_s\rangle - \frac{a_s}{a_l} |\hat{e}_l\rangle, \quad \text{for all } s \neq l \quad (20)$$

but this correction vanishes in the thermodynamic limit.

Thus, we have shown that even for Hookian springs, altering a single contact in the thermodynamic limit cannot change the density of states [13]. For extended modes, eigenvalues can change by at most order N^{-1} and mode mixing is allowed only between modes whose eigenvalue spacing is less than N^{-1} . While localized modes that overlap with the altered contact can have a non-negligible change in eigenvalue and mix with a large number of extended modes, the density of such localized states vanishes as N^{-1} .

So far we have considered the effect of changing a single contact. In the thermodynamic limit, however, a small displacement would not alter just a single contact; instead, an extensive number of contacts would change (*i.e.*, $\Delta N_c \sim N$, where ΔN_c is the total number of altered contacts). However, the displacement amplitude can always be made small enough so that $\Delta N_c/N \ll 1$. In this limit, the contact changes would be spatially separated and their effect on the density of states would at worst add. These effects would therefore scale as $\Delta N_c/N$, but since this can be made arbitrarily small, we conclude that the linear regime is well defined.

3. Numerical Verification

We now provide numerical evidence to support the analytical result that changing a single contact has a N^{-1} effect on the linear vibrational properties. To do this, we generate mechanically stable 2-dimensional packings of spheres that interact according to Eq. (1) with $\alpha = 2$. For each mechanically stable system, we first obtain the normal modes of vibration by diagonalizing the dynamical matrix D^0 . We then perturb the system by removing the weakest contact without actually displacing any particles. This perturbed system no longer corresponds to a sphere packing but allows us to isolate contact nonlinearities without considering expansion nonlinearities. The diagonalization of the resulting dynamical matrix \tilde{D} gives the normal modes of vibration for the perturbed system.

We compare the vibrational modes in Fig. 2 by projecting each mode $|\tilde{e}_n\rangle$ of the perturbed system onto each

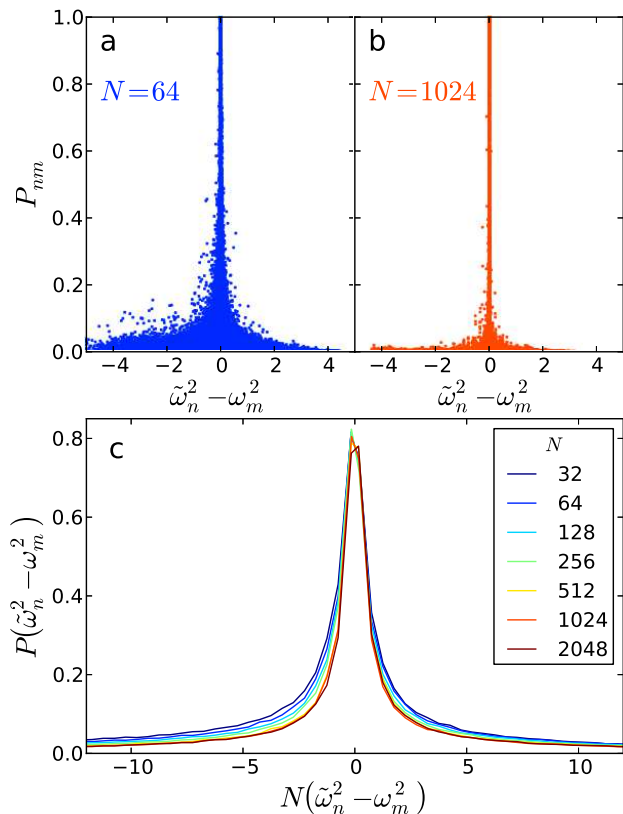

FIG. 2. The projection of a perturbed mode $|\tilde{e}_n\rangle$ onto the original modes $|\hat{e}_m\rangle$ as a function of the eigenvalue difference. a) 16 realizations of $N = 64$ particle systems. b) 1 realization of a $N = 1024$ particle system. All systems have Hookian interactions ($\alpha = 2$) in 2 dimensions and are at a pressure of 10^{-2} . c) The average projection as a function of $N(\tilde{\omega}_n^2 - \omega_m^2)$ for various system sizes. The range of $\tilde{\omega}_n^2 - \omega_m^2$ over which the projection is relevant vanishes slightly faster than N^{-1} .

mode $|\hat{e}_m\rangle$ of the unperturbed system. The projection

$$P_{nm} \equiv \langle \tilde{e}_n | \hat{e}_m \rangle \quad (21)$$

quantifies how close a perturbed mode is to an unperturbed mode. Fig. 2a shows a scatter plot of P_{nm} as a function of the difference in eigenvalue $\tilde{\omega}_n^2 - \omega_m^2$ for 16 systems of $N = 64$ particles at a pressure of 10^{-2} . Fig. 2b shows similar data but for a system of $N = 1024$ particles. As expected, the projection has a sharp peak at $\tilde{\omega}_n = \omega_m$, because mode mixing is stronger among modes of the same frequency.

The width of the peak in the projection is clearly smaller for the larger system. The N -dependence of the width is quantified in Fig. 2c, which shows the average projection, $P(\tilde{\omega}_n^2 - \omega_m^2)$, as a function of $N(\tilde{\omega}_n^2 - \omega_m^2)$. By comparing the width of $P(\tilde{\omega}_n^2 - \omega_m^2)$ at different system sizes, we see that it vanishes slightly faster than N^{-1} , confirming the fundamental result of our perturbation calculation above.

We can also measure the shift in vibrational frequency due to the removal of a single contact. The solid black

FIG. 3. Density of states for a single mechanically stable system ($D(\omega)$, solid black curve) and an identical system with a single contact removed ($D(\tilde{\omega})$, dashed red curve). The $N = 2048$ particle system has Hookian interactions and is at a pressure of 10^{-2} . The difference between the two density of states is well within the inherent fluctuations.

curve in Fig. 3 shows the density of vibrational states, $D(\omega)$, for a single mechanically stable $N = 2048$ particle system. The dashed red curve shows the density of states, $D(\tilde{\omega})$, for the corresponding perturbed system. While there is a small change, this difference is not systematic and is much smaller than the fluctuations inherent in the measurement. Since the density of states remains non-zero down to a characteristic frequency ω^* , which is related to the number of contacts above jamming, ΔZ [6, 7], changes to the contact network could have a more drastic effect if $\Delta Z \lesssim N^{-1}$. In the thermodynamic limit, however, this only occurs when $\Delta\phi \sim \Delta Z^2 \rightarrow 0$, *i.e.*, at the jamming transition, where nonlinear effects are known to dominate.

B. Continuity of the dynamical matrix for $\alpha > 2$

In the above perturbation argument, we looked at the effect of forming or breaking a contact on the eigenmodes and frequencies of the system. We exploited the sparsity of the perturbation matrix ΔD to show that the effects scale like N^{-1} , but we allowed the non-zero values of ΔD to be finite in magnitude. If these non-zero elements were vanishingly small, however, then the effect of altering the contact would be negligible and the above perturbation argument would not be necessary. We will see that this is the case for potentials where the dynamical matrix is a continuous function of the particle positions. In that case, the forming or breaking of a contact has a negligible effect on the response in the limit of small displacements.

We begin by considering the difference between the linear and nonlinear equations of motion (Eqs. (4) and

(7)). If we define $F_i^{\text{harm}}(\vec{u}) \equiv -D_{ij}^0 u_j$, then the quantity

$$\Delta F_i(\vec{u}) \equiv |F_i^{\text{harm}}(\vec{u}) - F_i(\vec{u})| / |F_i^{\text{harm}}(\vec{u})| \quad (22)$$

measures the relative error associated with the linearized equations of motion. If $\Delta F_i(\vec{u})$ remains “suitably” small, which again depends on the quantity being measured, then the harmonic approximation is justified and there is a valid linear regime.

Note that $|F_i^{\text{harm}}(\vec{u})|$ is clearly proportional to δ . Furthermore, using Eq. (5) we can write $F_i^{\text{harm}}(\vec{u}) - F_i(\vec{u}) = \int (D_{ij}(\vec{u}) - D_{ij}^0) du_j$, where $D_{ij}(\vec{u})$ are the elements of the instantaneous dynamical matrix at displacement \vec{u} . If all elements $D_{ij}(\vec{u}) - D_{ij}^0$ vanish in the limit $\delta \rightarrow 0$, then $F_i^{\text{harm}}(\vec{u}) - F_i(\vec{u})$ must vanish *faster* than δ and $\Delta F_i(\vec{u}) \rightarrow 0$ as $\delta \rightarrow 0$.

Also note that the instantaneous dynamical matrix can generically be written as

$$\begin{aligned} D_{ij}(\vec{u}) &\equiv \sum_{\text{contacts}} \frac{\partial^2 V(r)}{\partial r_i \partial r_j} \\ &= \sum_{\text{contacts}} k(r) \frac{\partial r}{\partial r_i} \frac{\partial r}{\partial r_j} - f(r) \frac{\partial^2 r}{\partial r_i \partial r_j}, \end{aligned} \quad (23)$$

where $f \equiv -\frac{\partial V(r)}{\partial r}$ and $k \equiv \frac{\partial^2 V(r)}{\partial r^2}$ are the force and stiffness of each contact, respectively, evaluated at \vec{u} . Therefore, we see that if $f(r)$ and $k(r)$ are continuous functions of the distance r between two particles, then $D_{ij}(\vec{u})$ is a continuous function of particle positions, which implies that $D_{ij}(\vec{u}) - D_{ij}^0$ vanishes for small δ and there is a valid linear regime.

Now, for one-sided interaction potentials of the form of Eq. (1), $f(r)$ is given by

$$f(r) \equiv \frac{\partial V(r)}{\partial r} = \begin{cases} \frac{\epsilon}{\sigma} \left(1 - \frac{r}{\sigma}\right)^{\alpha-1} & \text{if } r < \sigma \\ 0 & \text{if } r \geq \sigma \end{cases} \quad (24)$$

and $k(r)$ is given by

$$\begin{aligned} k(r) &\equiv \frac{\partial^2 V(r)}{\partial r^2} \\ &= \begin{cases} \frac{\epsilon(\alpha-1)}{\sigma^2} \left(1 - \frac{r}{\sigma}\right)^{\alpha-2} & \text{if } r < \sigma \\ 0 & \text{if } r \geq \sigma \end{cases}. \end{aligned} \quad (25)$$

$f(r)$ and $k(r)$ are both continuous when $r < \sigma$ and when $r > \sigma$; it is the point of contact ($r = \sigma$) that poses a potential problem. Discontinuities do indeed arise when the exponent α is less than or equal to 2, but $f(r)$ and $k(r)$, and thus $D_{ij}(\vec{u})$, are clearly continuous whenever $\alpha > 2$. Thus, there is always a valid linear regime for interaction potentials with $\alpha > 2$ [13].

We can calculate a lower bound for the size of the linear regime by requiring that the change in any element of $D_{ij}(\vec{u})$ never exceeds some ΔD_{max} . This is satisfied if the change in $k(r)$ of any bond never exceeds ΔD_{max} . From Eq. (25), we see that the maximum change in contact

length, Δr_{\max} , is given by

$$\frac{\Delta r_{\max}}{\sigma} = \left(\frac{\Delta D_{\max} \sigma^2}{\epsilon (\alpha - 1)} \right)^{1/(\alpha-2)}. \quad (26)$$

Therefore, if $\delta \langle \hat{u} | r \rangle$ is the projection of the displacement onto the bond length r , then the system has a well-defined linear regime for $\delta < \delta_0$ [13], where

$$\delta_0 = \Delta r_{\max} / \langle \hat{u} | r \rangle. \quad (27)$$

This statement is valid for any potential $\alpha > 2$ and is independent of the number of contacts that change or the system size. Importantly, the limit $\alpha \rightarrow 2^+$ is still well-behaved so that it is only in the case $\alpha = 2$ that $\delta_0 = 0$ and we must resort to the perturbation argument presented above in Sec. III.

In Ref. [19], Schreck *et al.* showed that for systems with Hertzian interactions, contact nonlinearities have a smooth effect on the spectral density as δ increases above δ_c , the minimum displacement magnitude required to change the contact network. This implies that although $\delta_c \rightarrow 0$ in the thermodynamic limit, the harmonic approximation should still describe small amplitude perturbations, in complete agreement with our results. The smooth onset of contact nonlinearities for $\alpha > 2$ also implies that, provided the time scale of the measurement is suitable, low amplitude *microscopic* measurements, for which $\delta < \delta_0$, can also be described by linear response. The issue of time scales is important and is discussed in the next section.

IV. NONZERO-AMPLITUDE VIBRATIONS AND TIME SCALES

So far, by considering infinitesimal vibrations, we have shown that linear response can accurately describe the lowest-order behavior of bulk quantities. However, since experiments must study nonzero-amplitude perturbations, it is also important to understand how nonlinearities affect the response.

For the cases of one-sided Hookian ($\alpha = 2$) [12] and Hertzian [19] springs, Schreck *et al.* investigated the effect of contact nonlinearities on the response to finite-amplitude vibrations. Specifically, they displaced a mechanically stable packing by $\delta \hat{e}_n$, where \hat{e}_n is an eigenmode of the dynamical matrix, and let the system evolve at constant energy. They measured the response from the spectral density and found dramatic mode mixing whenever the contact network changed during the oscillations, *i.e.*, when $\delta \geq \delta_c$.

For large amplitude vibrations, Schreck *et al.* showed that the spectral density is peaked at low frequencies. However, they incorrectly describe this as the density of vibrational modes. Normal modes of vibration are *defined* from the harmonic approximation, and while one can argue whether or not vibrational modes are relevant to larger vibrations, one *cannot* claim that nonlinearities

alter quantities such as the density of states that are only defined in the harmonic approximation [13].

Schreck *et al.* [12] claim that δ_c represents the “onset of nonharmonicity” for systems with Hookian interactions. However, this cannot be true since we have shown that δ_c does not mark the onset of *expansion* nonlinearities (see Fig. 1), which are always present for any density, system size, potential or displacement amplitude. Even for $\alpha = 2$, the dN dimensional energy basin always has higher-order nonlinearities. In addition, expansion nonlinearities exist for packings of particles with interactions that do not possess contact nonlinearities, such as the Lennard-Jones interaction.

The presence of nonlinearities at any amplitude implies that energy along a given mode will leak into other modes over time, regardless of whether δ is greater or less than δ_c . Importantly, mode mixing is a generic feature of finite-amplitude vibrations and is *not* an indication that there is no linear regime [1]. Therefore, an important factor is the time scale over which a measurement is made – although mode mixing is ubiquitous, the effect might not be noticeable over short times. Even when a contact forms or breaks, energy does not leak out of a mode immediately; Schreck *et al.* showed that the nonlinear behavior that they observe just above δ_c does not develop immediately but instead builds up over many oscillations [12]. Thus, the onset amplitude of nonlinear behavior depends sensitively on the time scale of the calculation. The harmonic approximation accurately predicts the full vibrational response over sufficiently short time scales.

For finite packings below δ_c , mode mixing still occurs due to expansion nonlinearities, but the time scale over which this happens is presumably much longer. Although Schreck *et al.* claim that “nonharmonicity stemming from the third and higher order terms occur for amplitudes $\delta \gg \delta_c$ ” [22], it is more correct to say that the effect of such nonlinear terms is only noticeable on the time scale of their simulations for amplitudes $\delta \gg \delta_c$, at which point contact nonlinearities are already prominent.

V. DISCUSSION

We have shown that jammed sphere packings always have a well-defined linear regime regardless of system size whenever $\Delta\phi > 0$, thus providing sound justification for the use of the harmonic approximation in the study of bulk response. This result contradicts the conclusion drawn by Schreck *et al.* [12] that there is no linear regime in the thermodynamic limit. That claim was based on their result that δ_c , which marks the onset of contact nonlinearities, vanishes as $N \rightarrow \infty$. However, as we showed in Sec. III, individual contact nonlinearities have a vanishing effect on bulk response in the thermodynamic limit. When measuring microscopic quantities like the evolution over time after a specific perturbation, Schreck *et al.* [12, 19] showed that nonlinear effects are

indeed important in jammed packings, just as they are for crystals. Nevertheless, we have shown that they are *not* essential for understanding bulk response to leading order.

Note that while there is a linear regime in the thermodynamic limit for $\Delta\phi > 0$ for any potential, the argument is most subtle for the case of Hookian repulsions ($\alpha = 2$). In Ref. [12], Schreck *et al.* focused on $\alpha = 2$ “so that the power law of the interaction force does not cause nonharmonic behavior.” As we have seen, however, the onset of contact nonlinearities is smooth when $\alpha > 2$ and thus has the potential to cause problems only when $\alpha \leq 2$. This leads to the interesting and counterintuitive result that nonlinear pair potentials are more harmonic than one-sided linear springs.

Our results also provide context for the recent work of Ikeda *et al.* [18], who studied nonlinearities that arise from thermal fluctuations. They find that nonlinearities begin to modify the linear vibrations when the fluctuations in the distance between neighboring particles is comparable to the width of the first peak of the radial distribution function. This observation, which suggests that an extensive number of contacts must form or break before the linear regime breaks down, is in complete agreement with our results.

Although expansion nonlinearities guarantee that the density of normal modes differs from the infinite-time spectral density of finite-amplitude vibrations, the harmonic approximation nonetheless provides the foundation from which we can understand such nonlinear behavior. Indeed, many aspects of nonlinear response are

strongly correlated with linear-response properties. For example, the Gruneisen parameter, an anharmonic property, depends on mode frequency, a harmonic property, in a way that is understood [16]. The energy barrier to rearrangement in a given mode direction is strongly correlated with mode frequency as well [16], and the spatial location of particle rearrangements is strongly correlated with high-displacement regions in quasi-localized low-frequency modes [23–25].

Even at the onset of jamming, where the linear regime vanishes, it is essential to understand the linear response in order to approach the nonlinear response. This is illustrated by a recent analysis of shock waves in marginally jammed solids [17]. The importance of linear quantities in the presence of a vanishingly small linear regime is not unique to jamming. In the Ising model, for example, the magnetic susceptibility diverges at the critical point, but the linear theory is still central to our understanding of the phase transition. Just as one must first understand phonons to understand phonon-phonon scattering, the density of normal modes and other linear response properties provide essential insight into the nature of jammed solids.

We thank Justin Burton, Lisa Manning, Samuel Schoenholz, Anton Souslov and Daniel Sussman for important discussions.
